Abstract

Computational grids are characterized by their dynamic, non-dedicated, and heterogeneous nature. Novel application-level and middleware-level techniques are needed to allow applications to reconfigure themselves and adapt automatically to their underlying execution environments to be able to benefit from computational grids’ resources. In this paper, we introduce a new software framework that enhances the Message Passing Interface (MPI) performance through process checkpointing, migration, and an adaptive middleware for load balancing. Fields as diverse as fluid dynamics, material science, biomechanics, and ecology make use of parallel adaptive computation where target architectures have traditionally been supercomputers and tightly coupled clusters. Our framework is a first step in allowing these computations to use computational grids efficiently. Our results demonstrate that application reconfiguration through middleware-triggered process migration improves dramatically the performance of MPI applications.

1 Introduction

Computational grids [16] have become very attractive platforms for high performance distributed applications due to their high availability, scalability, and computational power. However, nodes in grid environments, such as individual processors or SMPs, are not necessarily dedicated to a single parallel or distributed application. They experience constantly changing loads and communication demands. Achieving the desired high performance, requires augmenting applications with appropriate support for reconfiguration and adaptability to the dynamic nature of computational grids.

Scientific and engineering distributed and parallel applications have a complex nature. They are computationally demanding, involve solving or simulating multi-scale problems with dynamic behavior, and often require sophisticated adaptive methods and dynamic load balancing techniques to achieve high performance. In particular, engineering applications that arise extensively in diverse disciplines such as fluid dynamics, material science, biomechanics, and ecology require a continuous adaptation of meshes and numerical methods to achieve specified levels of solution accuracy [7]. These challenges have been addressed by complex application-level load balancing algorithms and adaptive refinement techniques [9]. However, most existing solutions assume either a static number of cooperating processes or dedicated resources. Running such applications on computational grids introduces additional challenges that cannot be addressed sufficiently by application-level load balancing.

MPI [20] has been widely adopted as the de-facto standard to implement parallel and distributed applications that harness several processors. However, the issues of scalability, adaptability, and load balancing still remain a challenge. Most existing MPI implementations assume a static network environment. MPI implementations that support the MPI-2 standard [17, 21] provide partial support for dynamic process management, but still require complex application development from end-users: process management needs to be handled explicitly at the application level, which requires the developer to deal with issues such as resource discovery and allocation, scheduling, load balancing, etc. Additional middleware-support is therefore needed to relieve application developers from non-functional concerns such as load balancing through application reconfiguration.

In this paper, we introduce MPI/IOS, a middleware in-
framework that permits the automatic reconfiguration of MPI applications in a dynamic setting. The Internet Operating System (IOS) [8] is a distributed middleware framework that provides opportunistic load balancing capabilities through resource-level profiling and application-level profiling. MPI/IOS adopts a semi-transparent checkpointing mechanism, where the user needs only specify the data structures to save and restore to facilitate process migration. This approach does not require extensive code modifications and allows legacy MPI applications to benefit from load balancing features by just inserting a small number of API calls. In shared environments where many applications are running, having application-level resource management is not enough to efficiently balance the load of the entire system. A middleware layer is the natural location where to place OS-like resource management of several applications running simultaneously.

We believe that providing simple APIs and delegating most of the load distribution and balancing to middleware will allow smooth and easy migration of MPI applications from static and dedicated clusters to highly dynamic computational grids. Our framework is more beneficial for long running applications involving large numbers of machines, where the probability of load fluctuations is high. In such situations, it will be helpful for the running application to have means by which to evaluate continuously its performance, discover new resources, and be able to migrate whole or parts of the application to better nodes. We target initially highly synchronized iterative applications that have the unfortunate property of running as slow as the slowest process. Eliminating the slowest processor from the computation results, in most cases, in an overall improved performance.

The remainder of the paper is organized as follows. Section 2 presents related work. In Section 3, we describe the approach of MPI/IOS. Section 4 details the architecture of the framework. In Section 5, we present experimental results. We conclude with discussion and future work in Section 6.

2 Related Work

There are a number of conditions that can introduce computational load imbalances during the lifetime of an application: 1) the application may have irregular or unpredictable workloads from, e.g., adaptive refinement, 2) the execution environment may be shared among multiple users and applications, and/or 3) the execution environment may be heterogeneous, providing a wide range of processor speeds, network bandwidth and latencies, and memory capacity. Dynamic load balancing (DLB) is necessary to achieve a good parallel performance when such imbalances occur. Most DLB research has targeted the application level (e.g., [9, 12, 15]), where the application itself continuously measures and detects load imbalances and tries to correct them by redistributing the data, or changing the granularity of the problem through domain repartitioning. Although such approaches have proved beneficial, they suffer from several limitations. First they are not transparent to application programmers. They require complex programming and are domain specific. Second, they require applications to be amenable to data partitioning, and therefore will not be applicable in areas that require rigid data partitioning. Lastly, when these applications are run on the more dynamic grid, application-level techniques which have been applied successfully to heterogeneous clusters [12, 14] may fall short in coping with the high fluctuations in resource availability and usage. Our research targets middleware-level DLB which allows a separation of concerns: load balancing and resource management are transparently dealt with by the middleware, while application programmers deal with higher level domain specific issues.

Several recent efforts have focused on middleware-level technologies for the emerging computational grids. Adaptive MPI (AMPI) [4, 18] is an implementation of MPI on top of light-weight threads that balances the load transparently based on a parallel object-oriented language with object migration support. Load balancing in AMPI is done through migrating user-level threads that MPI processes are executed on. This approach limits the portability of process migration across different architectures since it relies on thread migration. Process swapping [22] is an enhancement to MPI that uses over-allocation of resources and improves performance of MPI applications by allowing them to execute on the best performing nodes. Our approach is different in that we do not need to over-allocate resources initially. Such a strategy, though potentially very useful, may be impractical in grid environments where resources join and leave and where an initial over-allocation may not be possible. We allow new nodes that become available to join the computational grid to improve the performance of running applications during their execution.

Other efforts have focused on process checkpointing and restart as a mechanism to allow applications to adapt to changing environments. Examples include CoCheck [23], starFish [1], and the SRS library [24]. Both CoCheck and starFish support checkpointing for fault-tolerance, while we provide this feature to allow process migration and hence load balancing. SRS supports this feature to allow application stop and restart. Our work differs in the sense that we support migration at a finer granularity. Process checkpointing is a functional concern that is needed to allow dynamic reconfiguration. To be able to migrate MPI processes to better performing nodes, processes need to save their state, migrate, and restart from where they left off. Application-transparent process checkpointing is not a trivial task and
can be very expensive, as it requires saving the entire process state. Semi-transparent checkpointing provides a simple solution that has been proved useful for iterative applications [22, 24]. API calls are inserted in the MPI program that informs the middleware of the important data structures to save. This is an attractive solution that can benefit a wide range of applications and does not incur significant overhead since only relevant state is saved.

3 An Approach for Dynamically Reconfiguring MPI Applications

Traditional MPI programs are designed with dedicated resources in mind. Developers need to know initially what resources are available and how to assign them to MPI processes. To permit a smooth migration of existing MPI applications to dynamic grid environments, MPI runtime environments should be augmented with middleware tools that free application developers from concerns about what resources are available and when to use them. Simply acquiring the resources is not enough to achieve peak MPI performance. Effective scheduling and load balancing decisions need to be performed continuously during the lifetime of a parallel application. This requires the ability to profile application behavior, monitor the underlying resources, and perform appropriate load balancing of MPI processes through process migration.

Process migration is a key requirement to enable malleable applications. We describe in what follows how we achieve MPI process migration. We then introduce our middleware-level support.

3.1 MPI Process Migration

MPI processes periodically get notified by the middleware if a migration or a reconfiguration request has been received. When a process receives a migration notification, it immediately initiates checkpointing of its local data. Checkpointing is achieved through library calls that are inserted by the programmer in specific places in the application code. We currently support iterative applications since their iterative structure exhibits natural locations (at the beginning of each iteration) to place polling, checkpointing and resumption calls. When the process is first started, it checks whether it is a fresh process or it has been migrated. In the second case, it proceeds to data and process interconnectivity restoration.

In MPI, any communication between processes needs to be done as part of a communicator. An MPI communicator is an opaque object with a number of attributes, together with simple functions that govern its creation, use and destruction. An intracommunicator delineates a communication domain which can be used for point-to-point communications as well as collective communication among the members of the domain. While an intercommunicator allows communication between processes belonging to disjoint communicators. MPI process migration requires careful update of any communicator that involves the migrating process. A migration request forces all running MPI processes to enter a reconfiguration phase where they all cooperate to update their shared communicators. The migrating process spawns a new process in the target location and sends it its local checkpointed data. Figure 1 describes the steps involved in managing the MPI communicators for a sample process migration. In the original communicator, (Communicator 1), P7 has received a migration request. P7 cooperates with the processes of communicator 1 to spawn the new process, P0 in communicator 2, which will replace it. The intercommunicator that results from this spawning is merged into one global communicator. Later, the migrating process is removed from the old communicator and the new process is assigned rank 7. The new process restores the checkpointed data from its local daemon and regains the same state of the migrating process. All processes then get a handle to the new communicator and the application resumes its normal execution.

3.2 Middleware-level Support

Now that MPI processes are augmented with the ability to migrate, middleware support is needed to guide the application as to when it is appropriate to migrate processes and where to migrate them. IOS middleware analyzes both the underlying physical network resources and the application communication patterns to decide how applications should be reconfigured to accomplish load balancing and...
Figure 2. Architecture of a node in the Internet Operating System middleware (IOS). An agent collects profiling information and makes decisions on how to reconfigure the application based on its decisions, protocol, and profiling information.

Figure 4 shows an MPI/IOS computational node running MPI processes. A PCM daemon (PCMD) interacts with the IOS middleware and MPI applications. A PCMD is started in every node that actively participates in an application. A PCM dispatcher is used to start PCMDs in various nodes.

Figure 4. Architecture of a node running MPI/IOS enabled applications.
and used also to discover existing ones. PCMDs are designed following the client-server model. The application initially registers all MPI processes with their local daemons. The port number of a daemon is passed as an argument to mpiexec or read from a configuration file that resides in the same host.

Every PCMD has a corresponding IOS agent. There could be more than one MPI process in each node. The daemon consists of various services used to achieve process communication profiling, checkpointing and migration. The MPI wrapper calls record information pertaining to how many messages have been sent and received and their source and target process ranks. The profiled communication information is passed to the IOS profiling component. IOS agents keep monitoring their underlying resources and exchanging information about their respective loads.

When a node’s available resources fall below a predefined threshold or a new idle node joins the computation, a work steal packet is propagated among the actively running nodes. The IOS agent of a node responds to work stealing requests if it becomes overloaded and its decision component decides according to the resource management model which process(es) need(s) to be migrated. Otherwise, it forwards the request to an IOS agent in its set of peers. The decision component then notifies the reconfiguration service in the PCMD, which then sends a migration request to the desired process(es). At this point, all active PCMDs in the system are notified about the event of a reconfiguration. This causes all processes to cooperate until migration is completed and application communicators have been properly updated. Although this mechanism imposes some synchronization delay, it ensures that no messages are being exchanged while process migration is taking place and avoids incorrect behaviors of MPI communicators. Reconfiguration requests are sent to other processes in the MPI application by their corresponding PCMDs.

5 Experimental Results

We have used an MPI program that computes a two-dimensional heat distribution matrix to evaluate the performance of process migration. This application models iterative parallel applications that are highly synchronized and therefore require a frequent communication between the boundaries of the MPI processes. The original MPI code was manually instrumented by inserting PCM API calls to enable PCM checkpointing. It took 10 lines of PCM library calls to instrument this application, which consists originally of 350 lines of code.

The experimental test-bed consists of a multi-user cluster that consists of a heterogeneous collection of Sun computers running Solaris. We used a cluster of 20 nodes that consist of 4 dual-processor SUN Blade 1000 machines with 750 MHz per processor and 2 GB of memory, and 16 single-processor SUN Ultra 10 machines with 400 MHz and 256 MB of memory. We used the latest release of MPICH2 [2], a freely available implementation of the MPI-2 standard.

The goal of the first experiment was to determine the overhead incurred by the PCM API. The heat distribution program was executed using both MPICH2 and MPI/IOS with several numbers of nodes. We run both tests under a controlled load environment to make sure that the machine load is somehow balanced and no migration will be triggered by the middleware. Both implementations demonstrated similar performance. Figure 5 shows that the overhead of the PCM library is negligible.

The second experiment aims at evaluating the impact of process migration. The cluster of 4 dual-processor nodes was used. Figures 6 and 7 show the breakdown of the iteration execution time of the heat application using MPICH2 and MPI/IOS respectively. The load of the participating nodes was controlled to provide a similar execution environment for both runs. The application was allowed to run for a few minutes, after which the load of one of the nodes was artificially increased substantially. In Figure 6, the overall execution time of the application iterations increased. The highly synchronized nature of this application forces all the processes to become as slow as the one assigned to the slowest processor. The application took 203.97 seconds to finish. Figure 7 shows the behavior of the same application under the same load conditions using MPI/IOS. At iteration 260, a new node joined the computation. This resulted in migration of an MPI process from the overloaded node to the available new node. The figure shows how migration corrected the load imbalance. The application took 115.27 seconds to finish in this case, which is almost a 50% improvement over the non-adaptive MPICH2 run.

In a third experiment, we evaluated the adaptation of the heat application to changing loads. Figure 8 shows the behavior of the application’s throughput during its lifetime. The total number of iterations per second gives a good estimate of how good the application is performing for the class of highly synchronized applications. We run the heat program using the 4 dual-processor cluster and increased the load in one of the participating nodes. MPI/IOS helped the application to adapt by migrating the process from the slow node to one of the cooperating nodes. The application was using only 3 nodes after migration; however, its overall throughput improved substantially. The application executed twice as fast compared to MPICH2 under the same load conditions. In figure 9, we evaluated the impact of migration when a new node joins the computation. In this experiment, we used 3 fast machines and a slow machine. We increased the load of the slow machine while the application was running. The throughput of the application
increased dramatically when the slow process migrated to a fast machine that joined the IOS network. The heat program run five times faster than in the case of MPICH2.

6 Discussion and Future Work

This paper introduced several enhancements to MPI to allow for application reconfiguration and middleware-triggered dynamic load balancing. MPI/IOS improves MPI runtimes with a library that allows process-level checkpointing and migration. This library is integrated with an adaptive middleware that triggers dynamic reconfiguration based on profiled resource usage and availability. The PCM library has been initially introduced in previous work [11]. We have made major redesign and improvements over the previous work, where the PCM architecture was centralized and supported only application-level migration. The new results show major improvements in the scalability and performance. Our approach is portable and suitable for grid environments with no need to modify existing MPI implementations beyond the insertion of a small number of API calls.

Our preliminary version of MPI/IOS has shown that process migration and middleware support are necessary to improve application performance over dynamic networks. MPI/IOS is a first step in improving MPI runtime environments with the support of dynamic reconfiguration. Our implementation of MPI process migration can be used on top of any implementation that supports the MPI-2 standard. It could also be easily integrated with grid-enabled implementations such as MPICH-G2 [19] once they become MPI-2 compliant. Our load balancing middleware could be combined with several advanced checkpointing techniques (e.g., [3, 6, 13, 23]) to provide a better integrated software support.

for MPI application reconfiguration.

MPI/IOS is still a work in progress. Future work includes: 1) using the MPI profiling interface to discover communication patterns in order to provide a better mapping between application topologies and environment topologies, 2) evaluating different resource management models and load balancing decisions, 3) utilizing more effective checkpointing mechanisms, 4) extending our approach to support non-iterative applications, and 5) changing the granularity of running applications through automatic splitting and merging of executing processes, and 6) targeting more complex applications.
